**S** Supporting Information

**ABSTRACT:** Herein we report the mechanism of oxidative addition of CF<sub>3</sub>I to Au(I), and remarkably fast C<sub>aryl</sub>-CF<sub>3</sub> bond reductive elimination from Au(III) cations. CF<sub>3</sub>I undergoes a fast, formal oxidative addition to R<sub>3</sub>PAuR' (R = Cy, R' = 3,5-F<sub>2</sub>-C<sub>6</sub>H<sub>4</sub>, 4-F-C<sub>6</sub>H<sub>4</sub>, C<sub>6</sub>H<sub>5</sub>, 4-Me-C<sub>6</sub>H<sub>4</sub>, 4-MeO-C<sub>6</sub>H<sub>4</sub>, Me; R = Ph, R' = 4-F-C<sub>6</sub>H<sub>4</sub>, 4-Me-C<sub>6</sub>H<sub>4</sub>). When R' = aryl, complexes of the type R<sub>3</sub>PAu(aryl)(CF<sub>3</sub>)I can be isolated and characterized. Mechanistic studies suggest that near-ultraviolet light (λ<sub>max</sub> = 313 nm) photoinitiates a radical chain reaction by exciting CF<sub>3</sub>I. Complexes supported by PPh<sub>3</sub> undergo reversible phosphine dissociation at 110 °C to generate a three-coordinate intermediate that undergoes slow reductive elimination. These processes are quantitative and heavily favor C<sub>aryl</sub>-I reductive elimination over C<sub>aryl</sub>-CF<sub>3</sub> reductive elimination. Silver-mediated halide abstraction from all complexes of the type R<sub>3</sub>PAu(aryl)(CF<sub>3</sub>)I results in quantitative formation of Ar-CF<sub>3</sub> in less than 1 min at temperatures as low as -10 °C.

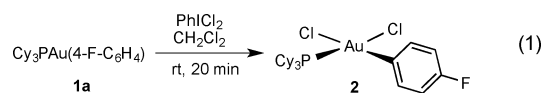

## INTRODUCTION

Reports of organogold complexes undergoing redox processes are typically limited to slow oxidative additions and reductive eliminations.<sup>1,2</sup> However, organogold complexes are not necessarily unreactive; we recently showed that diaryl Au(III) complexes undergo remarkably fast aryl-aryl reductive elimination at temperatures as low as -50 °C.<sup>3</sup> These recent findings from our group, as well those established by Vicente,<sup>4</sup> Hashmi,<sup>5</sup> and Lloyd-Jones,<sup>6</sup> suggest that the barrier for challenging reductive eliminations might be substantially diminished at Au(III). C<sub>aryl</sub>-CF<sub>3</sub> bond reductive elimination is typically a slow process requiring elevated temperatures and long reaction times, due to ground state stabilization afforded by exceptionally strong bonding between transition metals and CF<sub>3</sub> ligands.<sup>7</sup> For instance, (dppbz)Pd(2-Me-C<sub>6</sub>H<sub>4</sub>)(CF<sub>3</sub>) (dppbz = 1,2-bis(diphenylphosphino)benzene) is stable at 130 °C for 3 days,<sup>8</sup> while (dppp)Pd(Ph)(CF<sub>3</sub>) (dppp = 1,3-diphenylphosphinopropane) and (dppe)Pd(Ph)(CF<sub>3</sub>) (dppe = 1,2-diphenylphosphinoethane) yield only 10% PhCF<sub>3</sub> after 3 days at 145 °C.<sup>9</sup> Reductive eliminations at temperatures between 50 and 80 °C can be achieved at Pd(II) by employing bulky ligands, such as Xantphos<sup>10</sup> and Brettphos.<sup>11</sup> Notably, while aryl-CF<sub>3</sub> reductive eliminations from Pd(IV) often require similarly high temperatures,<sup>12a</sup> Sanford has shown that they can occur at temperatures as low as 23 °C over 1 h.<sup>12b</sup> Despite advances in catalytic trifluoromethylation, C<sub>aryl</sub>-CF<sub>3</sub> reductive elimination still remains a challenging step. Given the importance of trifluoromethylated arenes in pharmaceuticals and agrochemicals,<sup>13</sup> we were prompted to investigate potentially low-barrier C<sub>aryl</sub>-CF<sub>3</sub> bond reductive elimination at Au(III).

To access complexes of the type R<sub>3</sub>PAu(aryl)(CF<sub>3</sub>)I, we were drawn to Puddephatt's report of the oxidative addition of CF<sub>3</sub>I to Me<sub>3</sub>PAuMe to afford *cis/trans* mixtures of Me<sub>3</sub>PAuMe<sub>2</sub>(CF<sub>3</sub>) and Me<sub>3</sub>PAuI.<sup>14</sup> In one case, Me<sub>3</sub>PAu(Me)(CF<sub>3</sub>)I was obtained exclusively, but its preparation could not be reproduced by the authors. Because reaction times varied from 5 min to 1 day, and rates dramatically slowed in the presence of galvinoxyl, the authors concluded that a free-radical chain mechanism was operative, with •CF<sub>3</sub> as the propagating species.

## RESULTS AND DISCUSSION

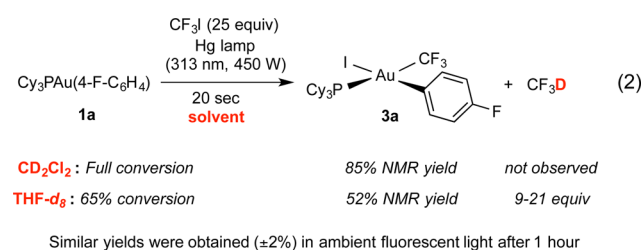

Prior investigations by our group revealed that oxidation of Ph<sub>3</sub>PAu(4-F-C<sub>6</sub>H<sub>4</sub>) rapidly generates 4,4'-difluorobiphenyl through a mechanism involving aryl group transfer.<sup>3</sup> However, the use of the bulkier PCy<sub>3</sub> prevents transfer of the arene ligand, instead resulting in clean, rapid oxidation of Cy<sub>3</sub>PAu(4-F-C<sub>6</sub>H<sub>4</sub>) (**1a**) to the isolable Au(III) complex *cis*-(Cy<sub>3</sub>P)Au(4-F-C<sub>6</sub>H<sub>4</sub>)Cl<sub>2</sub> (**2**) (eq 1).<sup>15</sup> Therefore, we began our inves-

tigations of Au(I) oxidation by CF<sub>3</sub>I using **1a**, with the fluorinated arene ligand also providing a convenient <sup>19</sup>F NMR handle. Treatment of **1a** in CD<sub>2</sub>Cl<sub>2</sub> with CF<sub>3</sub>I (25 equiv) afforded the product of formal CF<sub>3</sub>I oxidative addition **3a** in 1 h in good yield (eq 2 and Table 1). Both the CF<sub>3</sub> and PCy<sub>3</sub>

ligands (doublet at  $\delta = -24.5$  and quartet at  $\delta = 25.6$  in the <sup>19</sup>F and <sup>31</sup>P NMR spectra, respectively) provide diagnostic NMR signals (Table 2). The substantial coupling (<sup>3</sup>J<sub>P-F</sub> = 63 Hz) between fluorine and phosphorus are characteristic of a *trans* relationship between the CF<sub>3</sub> and phosphine ligands.<sup>14</sup> X-ray analysis of crystals of **3a** confirmed this stereochemical relationship around the square planar Au(III) (Figure 1A); other than the homoleptic anion [Au(CF<sub>3</sub>)<sub>4</sub>]<sup>-</sup>,<sup>16</sup> complex **3a** contains a rare example of a crystallographically characterized Au(III)–CF<sub>3</sub> bond. Complex **3a** is not only stable to air and water but can be purified by column chromatography as well.

**Mechanism of Oxidative Addition of CF<sub>3</sub>I.** The reaction of **1a** and CF<sub>3</sub>I represents a rare oxidation of Au(I) to Au(III) that directly installs potentially reactive Au(III)–carbon bonds.<sup>1</sup> During our attempts to monitor the oxidative addition by <sup>19</sup>F NMR, we found that no reaction occurred when the reaction mixture was placed inside the dark NMR spectrometer. However, when the reaction mixture was exposed to ambient fluorescent light for 5 min, the formation of **3a** was detected (~20%). Given the reliance of numerous methods on CF<sub>3</sub>I as a trifluoromethyl source,<sup>17</sup> we investigated its photochemical reactivity. Actinometry experiments were carried out to determine the overall quantum yield, using the Norrish II

fragmentation of valerophenone as a standard.<sup>18</sup> The oxidative addition of CF<sub>3</sub>I to **1a** was complete after 20 s of irradiation by a Hg vapor lamp (2 mM aq. K<sub>2</sub>CrO<sub>4</sub> optical filter; transmittance  $\lambda_{\text{max}} = 313$  nm), while the fragmentation of valerophenone ( $\Phi = 1$ ) took place over 24 h under identical conditions. This rate difference, in addition to the ability of ambient light to bring the reaction to full conversion over variable reaction times (between 15 min and 1 h), supports a radical chain reaction as the mechanism of Au(I) oxidation by CF<sub>3</sub>I.

The reaction of excess CF<sub>3</sub>I and **1a** is also fast in THF, but the conversion is never greater than 65% (52% yield of **3a**), even when irradiated by a Hg vapor lamp for 1 h (*vide infra*). Notably, an excess of fluoroform (HCF<sub>3</sub>) is generated in THF, regardless of the light source (only DCF<sub>3</sub> is formed when THF-d<sub>8</sub> is used). GC-MS analysis of reaction mixtures reveals several products of THF oxidation, likely formed by H• abstraction by •CF<sub>3</sub>.

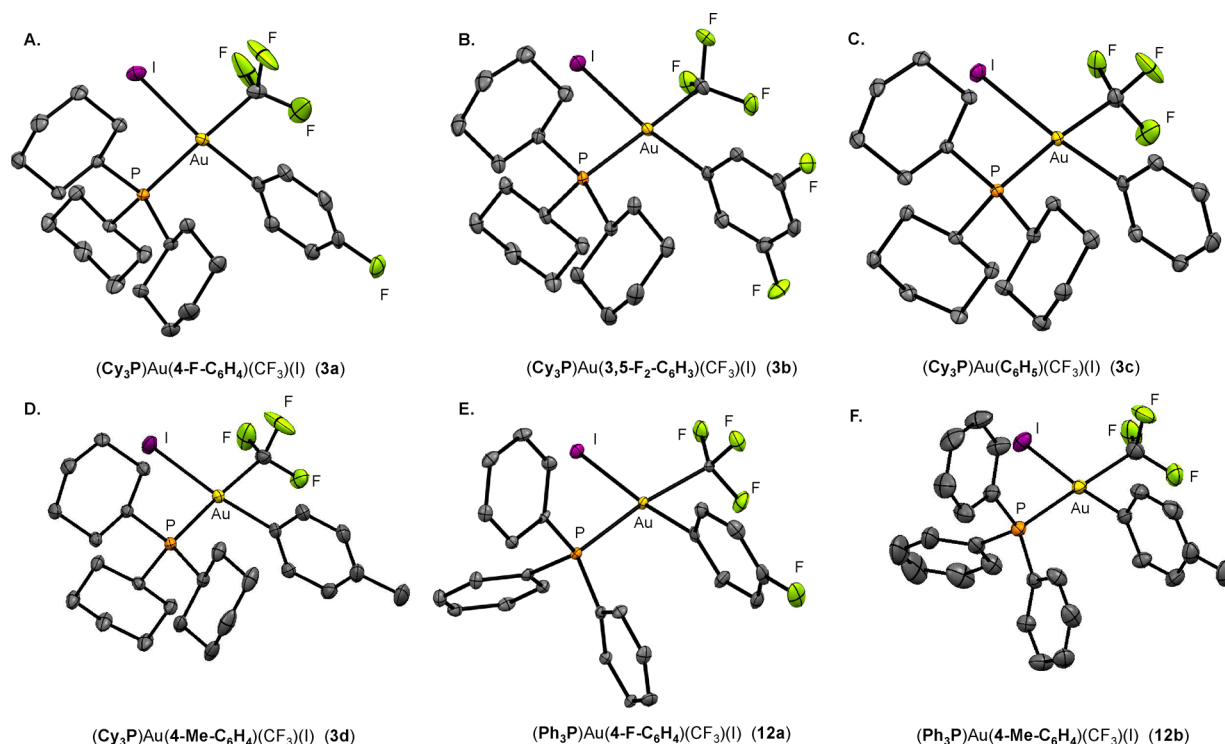

Several control experiments, using HCF<sub>3</sub> production relative to a standard as a probe to detect •CF<sub>3</sub> generation, support the involvement of Au(I) during the initiation of the chain reaction. The UV absorption of CF<sub>3</sub>I is centered at 270 nm but tails beyond 350 nm.<sup>19</sup> When irradiated at 313 nm, CF<sub>3</sub>I undergoes fast, reversible C–I bond homolysis. However, *in the absence of 1a*, only negligible amounts of HCF<sub>3</sub> are observed when THF solutions of CF<sub>3</sub>I are irradiated for 30 min, indicating that carbon/iodine radical recombination is substantially faster than H• abstraction from THF. Similarly insignificant quantities of HCF<sub>3</sub> are observed when 20 equiv (relative to CF<sub>3</sub>I) of the H• donors 1,4-cyclohexadiene, 9,10-dihydroanthracene, or triphenylmethane are added (Figure 2A). Additionally, Cy<sub>3</sub>PAu(2-(CH<sub>2</sub>CH=CH<sub>2</sub>)C<sub>6</sub>H<sub>4</sub>) (**4**), containing a pendent olefin to either capture a putative Au(II) intermediate and/or •CF<sub>3</sub>, is fully consumed upon irradiation in the presence of excess CF<sub>3</sub>I (Figure 2B). This oxidation affords multiple Au(III) products of indiscriminate •CF<sub>3</sub> addition to the terminal olefin and gold atom (and HCF<sub>3</sub> when THF is used as solvent) (see SI). Because 2-allylbromobenzene (**5**) does not react with CF<sub>3</sub>I when irradiated under similar conditions (no HCF<sub>3</sub> is observed after 5 min, and less than 2% after 30 min), we conclude that the Au(I) aryl complex is necessary for chain initiation. These results are also consistent with an initiation mechanism involving [CF<sub>3</sub>I]<sup>•+</sup>, which generates iodide and •CF<sub>3</sub> following C–I bond homolysis.

We envisioned two possible initiation mechanisms for generating •CF<sub>3</sub> as a propagating species from [CF<sub>3</sub>I]<sup>•+</sup> in a chain reaction: (1) initial photoexcitation of **6** followed by electron transfer to CF<sub>3</sub>I, or (2) initial photoexcitation of CF<sub>3</sub>I followed by electron transfer from **6** (Scheme 1).

**Figure 2.** Control experiments to assess involvement of Au(I) in the initiation of the radical chain mechanism. (A) Irradiation of  $\text{CF}_3\text{I}$  solutions containing  $\text{H}^\bullet$  donors to detect  $\text{CF}_3\text{H}$  in the absence of gold. (B) Radical trapping using an olefin with and without a pendant gold center.

Au(I) aryl complexes are well-known chromophores, and their photophysical properties have been investigated previously.<sup>20</sup> While **1a** absorbs weakly above 310 nm (the cutoff for many laboratory fluorescent lamps<sup>19</sup>), excitation at 320 nm ( $\epsilon = 37 \text{ M}^{-1} \text{ cm}^{-1}$ ) results in a weak, broad luminescence from 340 to 460 nm, classified as fluorescence based on the lifetime of excited species **1a\*** ( $<10 \text{ ns}$ , quantum yield of fluorescence = 0.03).<sup>21</sup> Despite the short lifetime of **1a\***,  $\text{CF}_3\text{I}$  effectively quenches its fluorescence (Stern–Volmer quenching constant  $K_{\text{SV}} = 30 \text{ M}^{-1}$ , Figure 3). Although this energy transfer could conceivably generate  $\cdot\text{CF}_3$  and initiate a chain reaction (mechanism 1, Scheme 1), when  $\text{CF}_3\text{I}$  is removed from

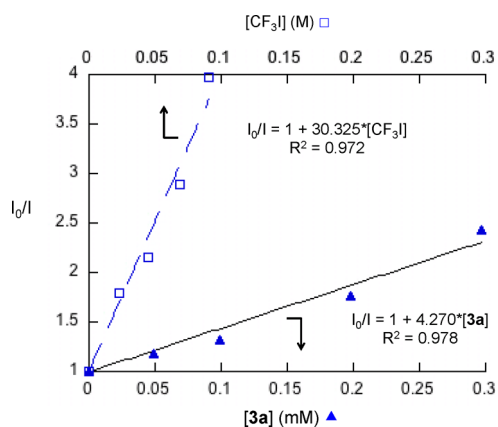

### Scheme 1. Possible Initiation Mechanisms Involving Photoexcitation of Either Au(I) Complex **6** (Mechanism 1) or $\text{CF}_3\text{I}$ (Mechanism 2)

fluorimetry samples under vacuum, fluorescence is restored to the same intensity prior to introduction of the gas, indicating that consumption of Au(I) has not occurred.

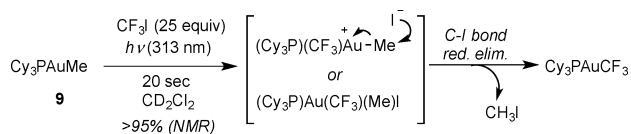

Surprisingly, fluorescence quenching by the Au(III) complex **3a** is more than 2 orders of magnitude more effective ( $K_{\text{SV}} = 4270 \text{ M}^{-1}$ ) than quenching by  $\text{CF}_3\text{I}$  (Figure 3). If propagating species terminate frequently, some critical concentration of Au(III) product exists that may impede productive energy transfer from an excited species, halting reinitiation of the chain reaction.

In light of Puddephatt's report, Au(I) alkyl complexes, such as  $\text{Me}_3\text{PAuMe}$ , clearly react with  $\text{CF}_3\text{I}$ .<sup>14</sup> However, there is no mention of the dependence of light on this process, although if the reaction is photoinitiated, mechanism 1 would seem especially unlikely given the absence of a chromophoric aryl ligand in Puddephatt's examples. To test this hypothesis, we irradiated  $\text{Cy}_3\text{PAuMe}$  (**9**) in the presence of  $\text{CF}_3\text{I}$  (Scheme 2).

**Figure 3.** Stern–Volmer plots of fluorescence quenching of **1a** by different concentrations of  $\text{CF}_3\text{I}$  (blue boxes) and Au(III) complex **3a** (blue triangles) in  $\text{CH}_2\text{Cl}_2$ . Concentrations of Au(III) are in mol/L and  $\text{CF}_3\text{I}$  concentrations are in mmol/L.

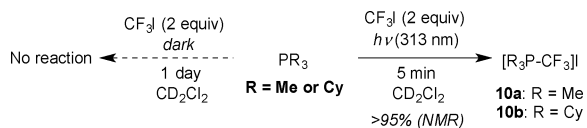

### Scheme 2. Photochemical Oxidative Addition of $\text{CF}_3\text{I}$ to **9** in $\text{CD}_2\text{Cl}_2$ and Spontaneous Reductive Elimination of $\text{CH}_3\text{I}$

While **9** does not absorb above 300 nm (see SI), the reaction is quantitative in  $\text{CD}_2\text{Cl}_2$  when irradiated with ambient light, and *does not proceed in the dark*. The oxidized product is unobservable, eliminating  $\text{CH}_3\text{I}$  to generate  $\text{Cy}_3\text{PAuCF}_3$  at room temperature.<sup>22,23</sup> In THF, the reaction generates excess HCF in THF, presumably also from solvent  $\text{H}^\bullet$  abstraction by  $^\bullet\text{CF}_3$ .

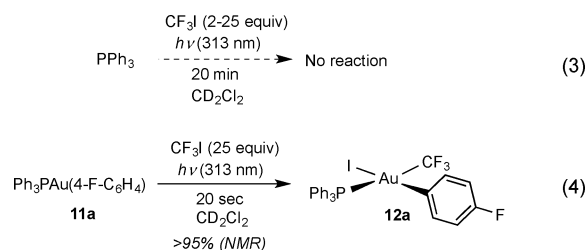

If initiation mechanism 2 is operative, then  $^\bullet\text{CF}_3$  could be generated by irradiating  $\text{CF}_3\text{I}$  solutions containing electron donors other than Au(I), such as phosphines (Scheme 3).<sup>24</sup>

### Scheme 3. Photochemical Oxidation of Trialkylphosphines by $\text{CF}_3\text{I}$

Indeed, irradiation of  $\text{PMe}_3$  or  $\text{PCy}_3$  in the presence of  $\text{CF}_3\text{I}$  results in formation of  $[\text{Me}_3\text{P-CF}_3]\text{I}$  (**10a**,  $^2J_{\text{P-F}} = 63$  Hz) or  $[\text{Cy}_3\text{P-CF}_3]\text{I}$  (**10b**,  $^2J_{\text{P-F}} = 42$  Hz);<sup>25</sup> neither reaction proceeds in the dark. Consistent with quenching of  $[\text{CF}_3\text{I}]^*$  by Au(III), the oxidation of  $\text{PCy}_3$  in THF stalls at roughly 45% conversion (by  $^{31}\text{P}$  NMR) in the presence of 25 mol % Au(III) complex **3a**.

$\text{PPh}_3$  does not react with  $\text{CF}_3\text{I}$  (eq 3), presumably due to its lower oxidation potential relative to  $\text{PMe}_3$  and  $\text{PCy}_3$ . When  $\text{PCy}_3$  and  $\text{PPh}_3$  are irradiated *together* with  $\text{CF}_3\text{I}$ , only  $\text{PCy}_3$  is consumed, suggesting that  $\text{PPh}_3$  neither initiates the chain nor reacts with  $^\bullet\text{CF}_3$  during propagation. Contrary to our initial hypothesis that bulky phosphine ligands prevent aryl group transfer upon Au(I) oxidation, we found that  $\text{Ph}_3\text{PAu}(4\text{-F-C}_6\text{H}_4)$  (**11a**) undergoes quantitative photoinitiated reaction with  $\text{CF}_3\text{I}$  in  $\text{CD}_2\text{Cl}_2$  to generate **12a** (eq 4). Since  $\text{PPh}_3$  is

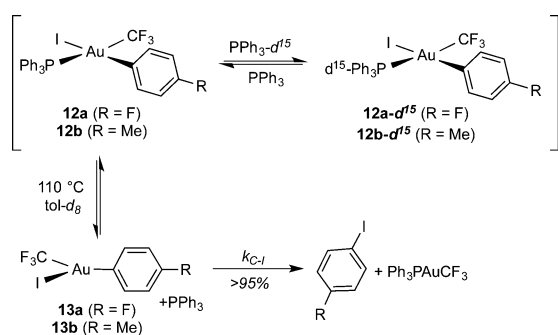

unreactive toward  $\text{CF}_3\text{I}$ , oxidation of **11a** cannot be initiated by small amounts of dissociated  $\text{PPh}_3$  (we cannot disprove the analogous mechanism for  $\text{PCy}_3$ -supported complex **1a**.) Complex **12a** was characterized by X-ray crystallography and shown to be isostructural to **3a** (Figure 1B).

On the basis of these results, we propose that while photoexcited  $[\text{CF}_3\text{I}]^*$  undergoes rapid C–I bond homolysis and recombination, it also oxidizes Au(I) aryl and alkyl complexes by accepting electrons into a low-lying SOMO to generate radical anion  $[\text{CF}_3\text{I}]^{\bullet-}$  (mechanism 2, Scheme 1). Homolysis of the C–I bond of  $[\text{CF}_3\text{I}]^{\bullet-}$  generates iodide and  $^\bullet\text{CF}_3$ , which oxidizes  $(\text{R}_3\text{P})\text{AuR}'$  (**6**) to Au(II) intermediate **7**. Iodine atom abstraction of  $\text{CF}_3\text{I}$  by **7** affords Au(III) complex **8** and regenerates  $^\bullet\text{CF}_3$ . In THF, oxidation of **6** by  $^\bullet\text{CF}_3$  is competitive with solvent  $\text{H}^\bullet$  abstraction to make HCF<sub>3</sub> and terminate the radical chain. At sufficiently high concentrations, the Au(III) product (**8**) quenches  $[\text{CF}_3\text{I}]^*$  before it can reinitiate the radical chain reaction.

Promisingly, the photoinitiated oxidative addition of  $\text{CF}_3\text{I}$  is general for electronically diverse complexes of the type  $\text{Cy}_3\text{PAu}(\text{aryl})$  (Tables 1 and 2). The resulting Au(III) products (see Figure 1 for their crystallographic analyses) can be purified by chromatography on silica. Complex **1b** (aryl = 3,5- $\text{F}_2\text{-C}_6\text{H}_3$ ), which is more electron-deficient than **1a** (aryl = 4- $\text{F-C}_6\text{H}_4$ ), reacts smoothly with  $\text{CF}_3\text{I}$  to afford **3b**. While complexes with more electron-rich ligands such as **1c** (aryl =  $\text{C}_6\text{H}_5$ ) and **1d** (aryl = 4- $\text{Me-C}_6\text{H}_4$ ) also react with  $\text{CF}_3\text{I}$  to afford **3c** and **3d**, respectively, the most electron-rich complex **1e** (aryl = 4- $\text{MeO-C}_6\text{H}_4$ ) decomposes to Au nano particles and several  $\text{CF}_3$ -containing Au(III) complexes in solution and solid state (no products of  $\text{C}_{\text{aryl}}\text{-I}$  or  $\text{C}_{\text{aryl}}\text{-CF}_3$  reductive elimination can be detected). Au(III) product **3e** is detectable, however, and its decomposition can be slowed substantially by addition of MeCN upon concentration of the reaction, allowing its solution-state characterization. The mechanism of decomposition has not yet been identified, although we speculate that the electron-rich arene may encourage  $\text{PCy}_3$  dissociation at room temperature and subsequent aryl group transfer.

The complex **1f** (aryl = 2- $\text{Me-C}_6\text{H}_4$ ) does not react with  $\text{CF}_3\text{I}$  at all, suggesting that  $\text{CF}_3\text{I}$  oxidative addition is sensitive to the sterics of the aryl ligand and that relaxation of  $[\text{CF}_3\text{I}]^*$  is faster than oxidation of the metal center to initiate the radical chain. Unsurprisingly, no HCF<sub>3</sub> is observed when **1f** is irradiated in THF for 20 min.

**Reductive Elimination from Au(III) Complexes.** We next probed  $\text{C}_{\text{aryl}}\text{-CF}_3$  reductive eliminations from Au(III). To our surprise, **12a** undergoes quantitative  $\text{C}_{\text{aryl}}\text{-I}$  reductive elimination in toluene- $d_8$  at 110 °C to afford 4-fluoroiodobenzene and  $\text{Ph}_3\text{PAuCF}_3$  over 20 min (Scheme 4).<sup>22</sup> No 4-fluoro(trifluoromethyl)benzene is observed by  $^{19}\text{F}$  NMR or GC. This process is highly sensitive to free phosphine, stalling completely in the presence of  $\text{PPh}_3$  (0.1 or 1.0 equiv) at 110 °C for 12 h. Treatment of **12a** with  $\text{PPh}_3\text{-}d_{15}$  at room temperature

Scheme 4. Behavior of Au(III) Complex 12a and 12b in the Presence of Free PPh<sub>3</sub> and at Elevated Temperatures

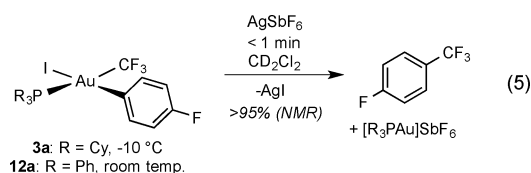

results in immediate formation of **12a-d<sub>15</sub>**, presumably via an associative process.<sup>2a-c</sup>

More electron-rich aryl ligands, such as 4-methylphenyl (**12b**), do not significantly affect the relative rates of C<sub>aryl</sub>-I and C<sub>aryl</sub>-CF<sub>3</sub> reductive elimination (Scheme 4). At 110 °C, complex **12b** undergoes mostly C<sub>aryl</sub>-I reductive elimination within 10 min to afford 4-methyliodobenzene.<sup>26</sup> Both C<sub>aryl</sub>-I and C<sub>aryl</sub>-CF<sub>3</sub> reductive eliminations are also completely inhibited in the presence of PPh<sub>3</sub> (0.1 or 1.0 equiv), while PPh<sub>3</sub>-d<sub>15</sub> reacts immediately at room temperature to afford **12b-d<sub>15</sub>**, also via associative ligand exchange. These observations are consistent with a mechanism involving highly reversible PPh<sub>3</sub> dissociation from **12a** and **12b**, followed by slow C<sub>aryl</sub>-I reductive elimination from **13a** or **13b**, respectively.

Clearly, the behaviors of **12a** and **12b** are similar to Au(III)alkyl complexes studied by Kochi, which not only reductively eliminate C<sub>alkyl</sub>-C<sub>alkyl</sub> bonds between 70 and 100 °C via a dissociative mechanism but also undergo associative ligand exchange at ambient temperature with excess phosphine.<sup>2a-c</sup> Unsurprisingly, analogous PCy<sub>3</sub>-stabilized complexes **3a** and **3d** are stable at 110 °C for at least 12 h, presumably due to the greater σ-donating ability of PCy<sub>3</sub> relative to PPh<sub>3</sub>. Phosphine exchange with excess P(*n*-Bu)<sub>3</sub>, PBn<sub>3</sub>, or PCy<sub>3</sub> does not occur even at these temperatures, precluding not only the lower-barrier associative exchange mechanism observed with the PPh<sub>3</sub>-supported systems (attributed to the larger cone angle of PCy<sub>3</sub> relative to PPh<sub>3</sub>), but also PCy<sub>3</sub> dissociation to form a three-coordinate complex.

Because C<sub>aryl</sub>-I reductive elimination is significantly faster than C<sub>aryl</sub>-CF<sub>3</sub> reductive elimination, a cycle for gold-catalyzed trifluoromethylation must necessarily involve iodide abstraction from the Au(III) product of CF<sub>3</sub>I oxidative addition. Despite the apparent kinetic stabilities of the Au(III) complexes **3a-3e**, **12a**, and **12b**, they all undergo quantitative C<sub>aryl</sub>-CF<sub>3</sub> reductive elimination in less than 1 min upon treatment with AgSbF<sub>6</sub> at room temperature.

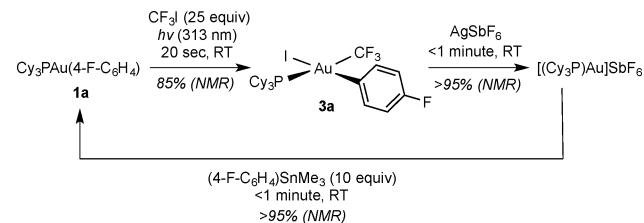

To consider the effects of the phosphine ligand on the silver-mediated C<sub>aryl</sub>-CF<sub>3</sub> reductive elimination of Au(III), we used variable-temperature NMR to follow the reductive elimination from **3a** and **12a** in the presence of AgSbF<sub>6</sub>. PCy<sub>3</sub>-substituted complex **3a** undergoes very fast (quantitative conversion in less than 1 min) C<sub>aryl</sub>-CF<sub>3</sub> reductive elimination at -10 °C, while the analogous PPh<sub>3</sub>-stabilized **12a** reacts similarly fast at room temperature (eq 5). At lower temperatures, several bridging species (most likely dimers) are observed by <sup>19</sup>F NMR upon halide abstraction in both cases. If C<sub>aryl</sub>-CF<sub>3</sub> bond reductive elimination can only occur from a monomeric three-coordinate intermediate, then **12a** might be expected to undergo slower

reductive elimination due to slower dimer dissociation and/or a dimer–monomer equilibrium that more favors the dimer, based on the smaller cone angle and weaker σ-donation of PPh<sub>3</sub> relative to PCy<sub>3</sub>.

## CONCLUSION

These results reported herein support the oxidative addition of CF<sub>3</sub>I to Au(I) via a photoinitiated chain reaction. The reactions are fast at room temperature for both Au(I) aryl and alkyl complexes. Aryl-CF<sub>3</sub> reductive elimination is typically a high-barrier process but occurs in seconds at room temperature from a Au(III) cation. The Au(I)aryl species may be regenerated via one of the numerous transmetalation strategies available involving carbon nucleophiles.<sup>27</sup> For instance, excess (4-F-C<sub>6</sub>H<sub>4</sub>)SnMe<sub>3</sub> (10 equiv) undergoes fast, quantitative transmetalation with [(Cy<sub>3</sub>PAu)SbF<sub>6</sub>] at room temperature to afford **1a**, thereby closing a hypothetical catalytic cycle based on the three elementary steps shown in Scheme 5. Silver-free halide

Scheme 5. Oxidation of 1a, Aryl-CF<sub>3</sub> Reductive Elimination, and Regeneration of 1a Supports the Feasibility of a Mild, Catalytic Trifluoromethylation

abstraction from Au(III) complexes could conceivably enable a practical and mild cycle for gold-catalyzed trifluoromethylation of aryl nucleophiles, although deleterious reactions between starting material and metalloradical intermediates and •CF<sub>3</sub> must be mitigated, as well as competitive aryl–aryl homocoupling.

While we initially set out to probe C<sub>aryl</sub>-CF<sub>3</sub> reductive elimination at Au(III), we also explored the oxidative addition of CF<sub>3</sub>I to Au(I), a process with potential implications beyond gold chemistry. The possibility of photoinitiated oxidation of transition metals or main group elements by CF<sub>3</sub>I should not be discounted in methods employing this reagent as a trifluoromethyl source, particularly since ambient fluorescent laboratory lighting is sufficient to initiate a chain in the presence of a suitable reductant. The results presented also suggest that substrate photoexcitation may provide a low-barrier avenue to kinetically challenging oxidative additions by Au(I), providing access to potentially reactive Au(III) complexes.<sup>28</sup>
