**Abstract** Featuring a high level of taxon sampling across *Ascomycota*, we evaluate a multi-gene phylogeny and propose a novel order and class in *Ascomycota*. We describe two new taxa, *Geoglossomycetes* and *Geoglossales*, to host three earth tongue genera: *Geoglossum*, *Trichoglossum* and *Sarcoleotia* as a lineage of 'Leotiomyceta'. Correspondingly, we confirm that these genera are not closely related to the genera *Neolecta*, *Mitula*, *Cudonia*, *Microglossum*, *Thuemenidium*, *Spathularia* and *Bryoglossum*, all of which have been previously placed within the *Geoglossaceae*. We also propose a non-hierarchical system for naming well-resolved nodes, such as 'Saccharomyceta', 'Dothideomyceta', and 'Sordariomyceta' for supraordinal nodes, within the current phylogeny, acting as rankless taxa. As part of this revision, the continued use of 'Leotiomyceta', now as a rankless taxon, is proposed.

### INTRODUCTION

The multi-gene sequence datasets generated by the research consortium 'Assembling the Fungal Tree of Life' (AFTOL) have resulted in several multi-gene phylogenies incorporating comprehensive taxon sampling across Fungi (Lutzoni et al. 2004, Blackwell et al. 2006, James et al. 2006). AFTOL generated a data matrix spanning all currently accepted classes in the *Ascomycota*, the largest fungal phylum. The phylogenies produced by AFTOL prompted the proposal of a phylogenetic classification from phylum to ordinal level in fungi (Hibbett et al. 2007). Although the Botanical Code does not require the principle of priority in ranks above family (McNeill et al. 2006), this principle was nevertheless followed for all taxa. The following ranked taxa were defined: subkingdom, phylum (suffix -mycota, except for Microsporidia), subphylum (-mycotina), class (-mycetes), subclass (-myctidae) and order (-ales). As in Hibbett et al. (2007), several phylogenetically well-supported nodes above the rank of order could not be accommodated in the current hierarchical classification system based on the International Code of Botanical Nomenclature. To remedy this deficiency, rankless (or unranked) taxa for unambiguously resolved nodes with strong statistical support was proposed (Hibbett & Donoghue 1998). Hybrid classifications that include both rankless and Linnaean taxa have since been discussed elsewhere (Jørgensen 2002, Kuntner & Agnarsson 2006), and applied to diverse organisms from lichens (Stenroos et al. 2002) and plants (Sennblad & Bremer 2002, Pfeil & Crisp 2005) to spiders (Kuntner 2006). These studies all attempt to create a comprehensive code for phylogenetic nomenclature that retains the current Linnean hierarchical codes.

In keeping with the practice of previous hybrid classifications, we propose to use names corresponding to clades of higher taxa that were resolved in this phylogeny as well as preceding studies.

The proposed informal, rankless names for well-supported clades above the class level in our phylogeny agrees with the principles of the PhyloCode (<http://www.ohio.edu/phylocode/>). It is our hope that such names should function as rankless taxa, facilitating the naming of additional nodes/clades as they become resolved. Eventual codification will follow the example of Hibbett et al. (2007) by applying principles of type names and priority. A number of published manuscripts already provide background on other supraordinal relationships of Fungi; for more complete treatments of the various classes, see Blackwell et al. (2006).

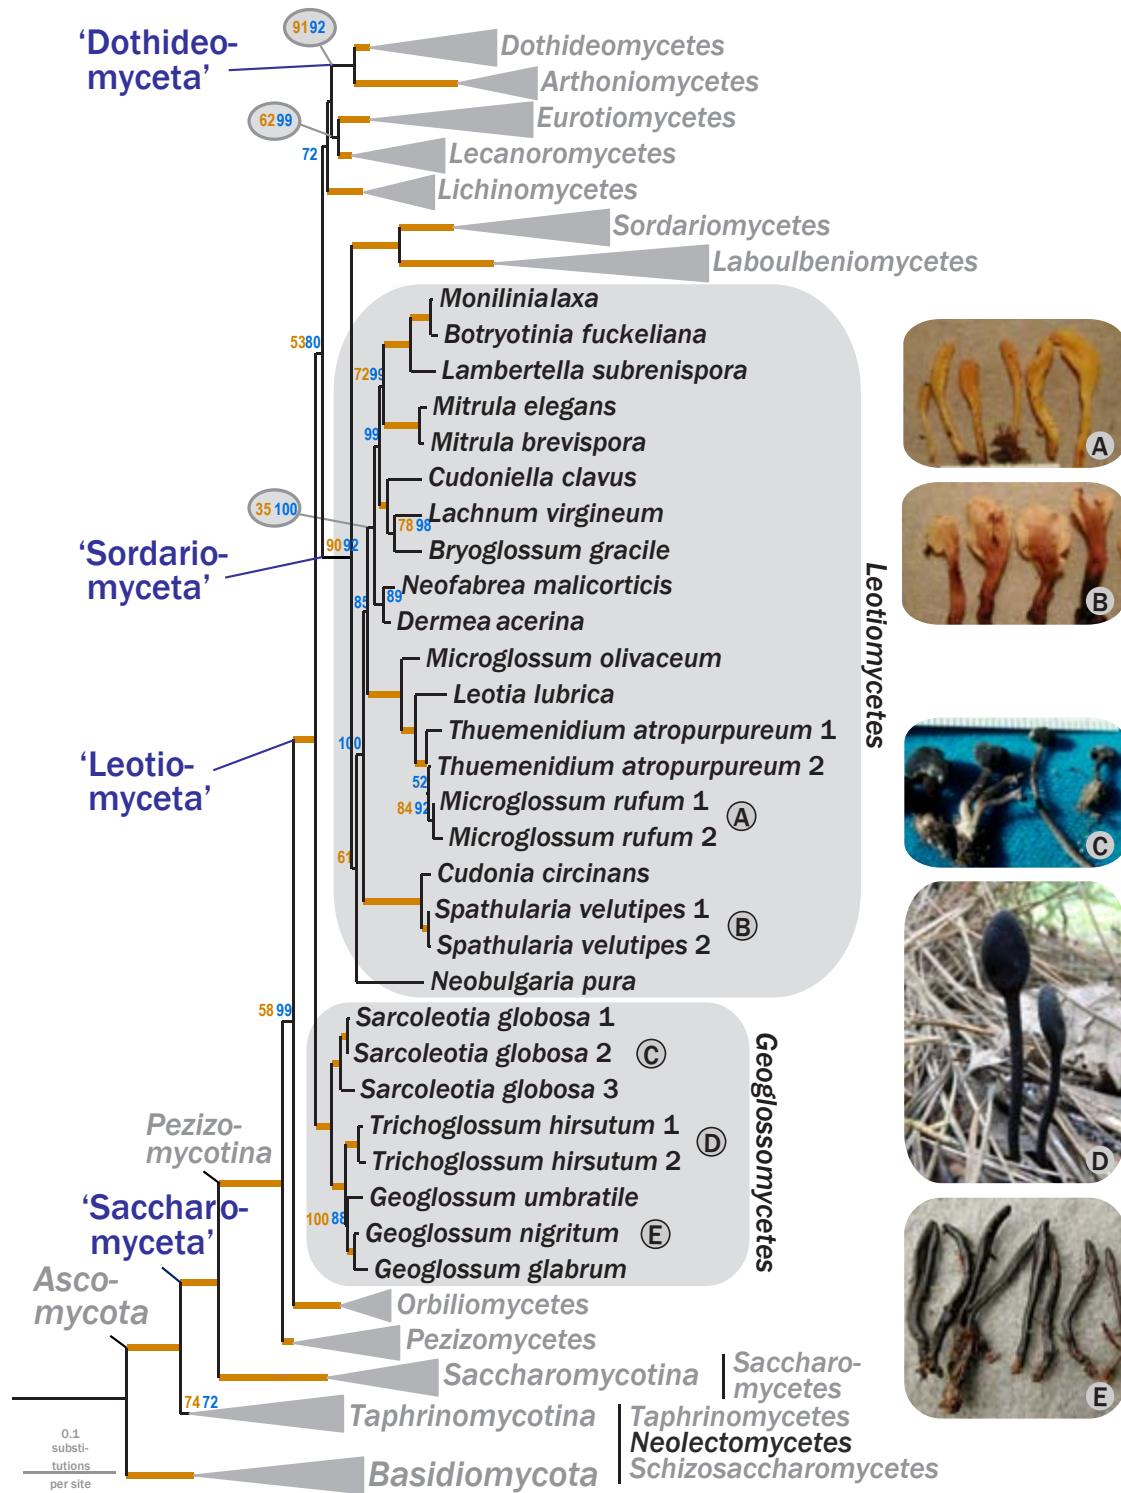

During the AFTOL project a data matrix was generated spanning all currently accepted classes in the *Ascomycota*, the largest fungal phylum. A multi-gene phylogeny was recently inferred from these data, demonstrating relevant patterns in biological and morphological character development as well as establishing several distinct lineages in *Ascomycota* (Schoch et al. 2009). Here we test whether the relationships reported in Schoch et al. (2009) remain valid by applying both maximum likelihood (ML) and Bayesian analyses on a more restricted but denser set of taxa, including expanded sampling in the *Geoglossaceae*.

We will therefore address the taxonomic placement of a group of fungi with earth tongue morphologies that are shown to be unrelated to other known classes. This morphology is closely associated with the family *Geoglossaceae* (Corda 1838). With typical inoperculate asci and an exposed hymenium, *Geoglossaceae* has long been thought to be a member of *Leotiomycetes*, though the content of the family itself has experienced many changes (Nannfeldt 1942, Korf 1973, Spooner 1987, Platt 2000, Wang et al. 2006a, b). It is currently listed with 48 species and 6 genera in the Dictionary of the Fungi (Kirk et al. 2008). Several analyses using molecular data supported a clade including three earth tongue genera, *Geoglossum*, *Trichoglossum* and *Sarcoleotia* (Fig. 1), and cast doubt upon their positions in *Leotiomycetes* (Platt 2000, Gernhardt et al. 2001, Lutzoni et al. 2004, Sandnes 2006, Spatafora et al. 2006, Wang et al. 2006b). Here we present a comprehensive phylum-wide phylogeny, including data from protein coding genes. We can confidently place the earth tongue family as separate from currently accepted classes in *Ascomycota*.

**Fig. 1** A most likely tree obtained by RAxML for Ascomycota. Subphyla, class and rankless taxa are indicated. Classes containing fungi designated as earth tongues are indicated in black. The tree was rooted with outlier *Rhizopus oryzae* (not shown). Bootstrap values are shown in orange and Bayesian posterior probabilities in blue. Orange, bold branches are supported by more than 80 % bootstrap and 95 % posterior probability, respectively. The full phylogeny, without collapsed clades, are shown in Fig. 2. The inset figures illustrate morphological ascospore diversity in the earth tongues. The species are as follows: A: *Trichoglossum hirsutum*; B: *Geoglossum nigritum*; C: *Microglossum rufum*; D: *Spathularia velutipes*; E: *Geoglossum nigritum*. ## MATERIALS AND METHODS

Data were extracted from the complete data matrix obtained from the WASABI database ([www.aftol.org](http://www.aftol.org)), incorporating representatives for all currently accepted classes, and maximizing the number of orders and available data. Following the approach of James et al. (2006) we performed a combined analysis, with both DNA and amino acid data, while allowing for missing data. This data was supplemented with additional ribosomal sequences from earth tongue genera obtained and

deposited in GenBank from two previous studies (Wang et al. 2006a, b). To further minimise poorly aligned areas, 219 additional columns, which proved variable when viewed in BioEdit with a 40 % shade threshold, were excluded from the original AFTOL inclusion set. The refined dataset consisted of 161 taxa (including outgroups) and 4 429 characters for six different loci: the nuclear small and large ribosomal subunits (nSSU, nLSU), the mitochondrial small ribosomal subunit (mSSU) and fragments from three proteins: transcription elongation factor 1 alpha (TEF1) and the largest and second largest subunits of

RNA polymerase II (*RPB1*, *RPB2*). A complete table with the published GenBank numbers is listed in Table 1.

The phylogenetic analysis was run in RAxML v7.0.0 (Stamatakis 2006), partitioning by gene (six partitions) and estimating unique model parameters for each gene, as in Schoch et al. (2009). Models of evolution were evaluated as in Schoch et al. (2009) with the same models selected. For DNA sequences, this resulted in a general time reversible model (GTR) with a discrete gamma distribution composed of four rate classes plus an estimation of the proportion of invariable sites. The amino acid sequences were analysed with a RTREV model with similar accommodation of rate heterogeneity across sites and proportions of invariant sites. In addition, protein models for *TEF1* and *RPB2* incorporated a parameter to estimate amino acid frequencies. The tree shown in Fig. 1 was obtained by using an option in RAxML running a rapid bootstrap analysis and search for the best-scoring ML tree in one single run. This meant the GTRCAT model approximation was used, which does not produce likelihood values comparable to other programs. The full tree is shown here as Fig. 2 and was deposited in TreeBASE (www.treebase.org). We also ran 100 repetitions of RAxML under a gamma rate distribution option. The best scoring tree was included in TreeBASE.

A second analysis was run using Bayesian inference of maximum likelihood in MrBayes v3.1.2 (Huelsenbeck & Ronquist 2001, Altekar et al. 2004) using models and parameters that were comparable to the maximum likelihood run. Data were similarly partitioned and amino acids were analysed, so that a mixture of models with fixed rate matrices for amino acid sequences could be evaluated. In all cases rate heterogeneity parameters were used by a discrete gamma distribution plus an estimation of the proportion of invariable sites. A metropolis coupled Markov Chain Monte Carlo analysis was run for 9 million generations sampling every 200th cycle, starting from a random tree and using 4 chains (three heated and one cold) under default settings. Two separate runs were confirmed to converge using Tracer v1.4.1 (<http://tree.bio.ed.ac.uk/software/tracer/>). The first 10 000 sampled trees (2 million generations) were removed as burn in each run. A 50 % majority rule consensus tree of 70 000 Bayesian likelihood trees from the two combined runs was subsequently constructed, and average branch lengths and posterior probabilities determined. The numbers of nodes shared with the most likely tree in Fig. 1 was determined and plotted on the branches. This tree was deposited in TreeBASE, along with the inclusive character set.

## RESULTS

The phylogeny presented in Fig. 1 supports 15 classes (11 in *Pezizomycotina*, 1 in *Saccharomycotina*, 3 in *Taphrinomycotina*) with good statistical support (both ML bootstrap and Bayesian posterior probability) for 14. Phylogenies with all lineages in the analysed data matrix are included in Fig. 2. A run with 100 repetitions of RAxML under a gamma rate distribution option resulted in a best scoring tree with a log likelihood of -111983. This tree shared the same supported nodes with the one presented in Fig. 1 but had changes in poorly supported nodes regarding placement of the *Eurotiomycetes* and *Dothideomycetes*. The two Bayesian runs produced trees with harmonic means of likelihood values of -112094 and -112076, respectively, with similar topological differences in poorly supported nodes.

As can be seen in Fig. 1, we continue to find low bootstrap and posterior probability support for *Leotiomycetes* as a monophyletic clade using a combined analysis of protein and nucleic acids. In our analysis, this includes *Neobulgaria pura* as the earliest diverging lineage. The node internal from this lineage

is found in all ML bootstrap trees, suggesting that this taxon is unstable in our analyses. No conflicts were detected in *Neobulgaria* genes under a previous study and missing data did not affect important nodes (Schoch et al. 2009). A repeat run under maximum likelihood was done with *Neobulgaria pura* removed under the same settings but with only 100 bootstrap repetitions. This trimmed dataset yielded a congruent phylogeny with increased bootstrap for *Leotiomycetes* (78 %; data not shown). The instability of the placement of *Neobulgaria pura* does not compromise any of the conclusions we present here and may be due to various reasons. Improved taxon sampling will likely help to resolve its placement in future analyses.

We find support for numerous backbone nodes in *Ascomycota*, as did Schoch et al. (2009). Our phylum-wide sampling of *Ascomycota* classes in this study, combined with the results of a previous study (Schoch et al. 2009), facilitated addressing the placement of the previously problematic and unsampled lineages such as the *Geoglossaceae* in relation to all currently accepted *Ascomycota* classes.

## Taxonomy

Given their unique ascatal development, ultrastructure of ascus apical apparatus, mossy habitat, and our multilocus gene phylogeny, *Geoglossomycetes* cl. & ord. nov. is justified here as incertae sedis in *Pezizomycotina* and 'Leotiomyceta'.

***Geoglossomycetes, Geoglossales*** Zheng Wang, C.L. Schoch & Spatafora, cl. & ord. nov. — MycoBank MB513351, MB513352

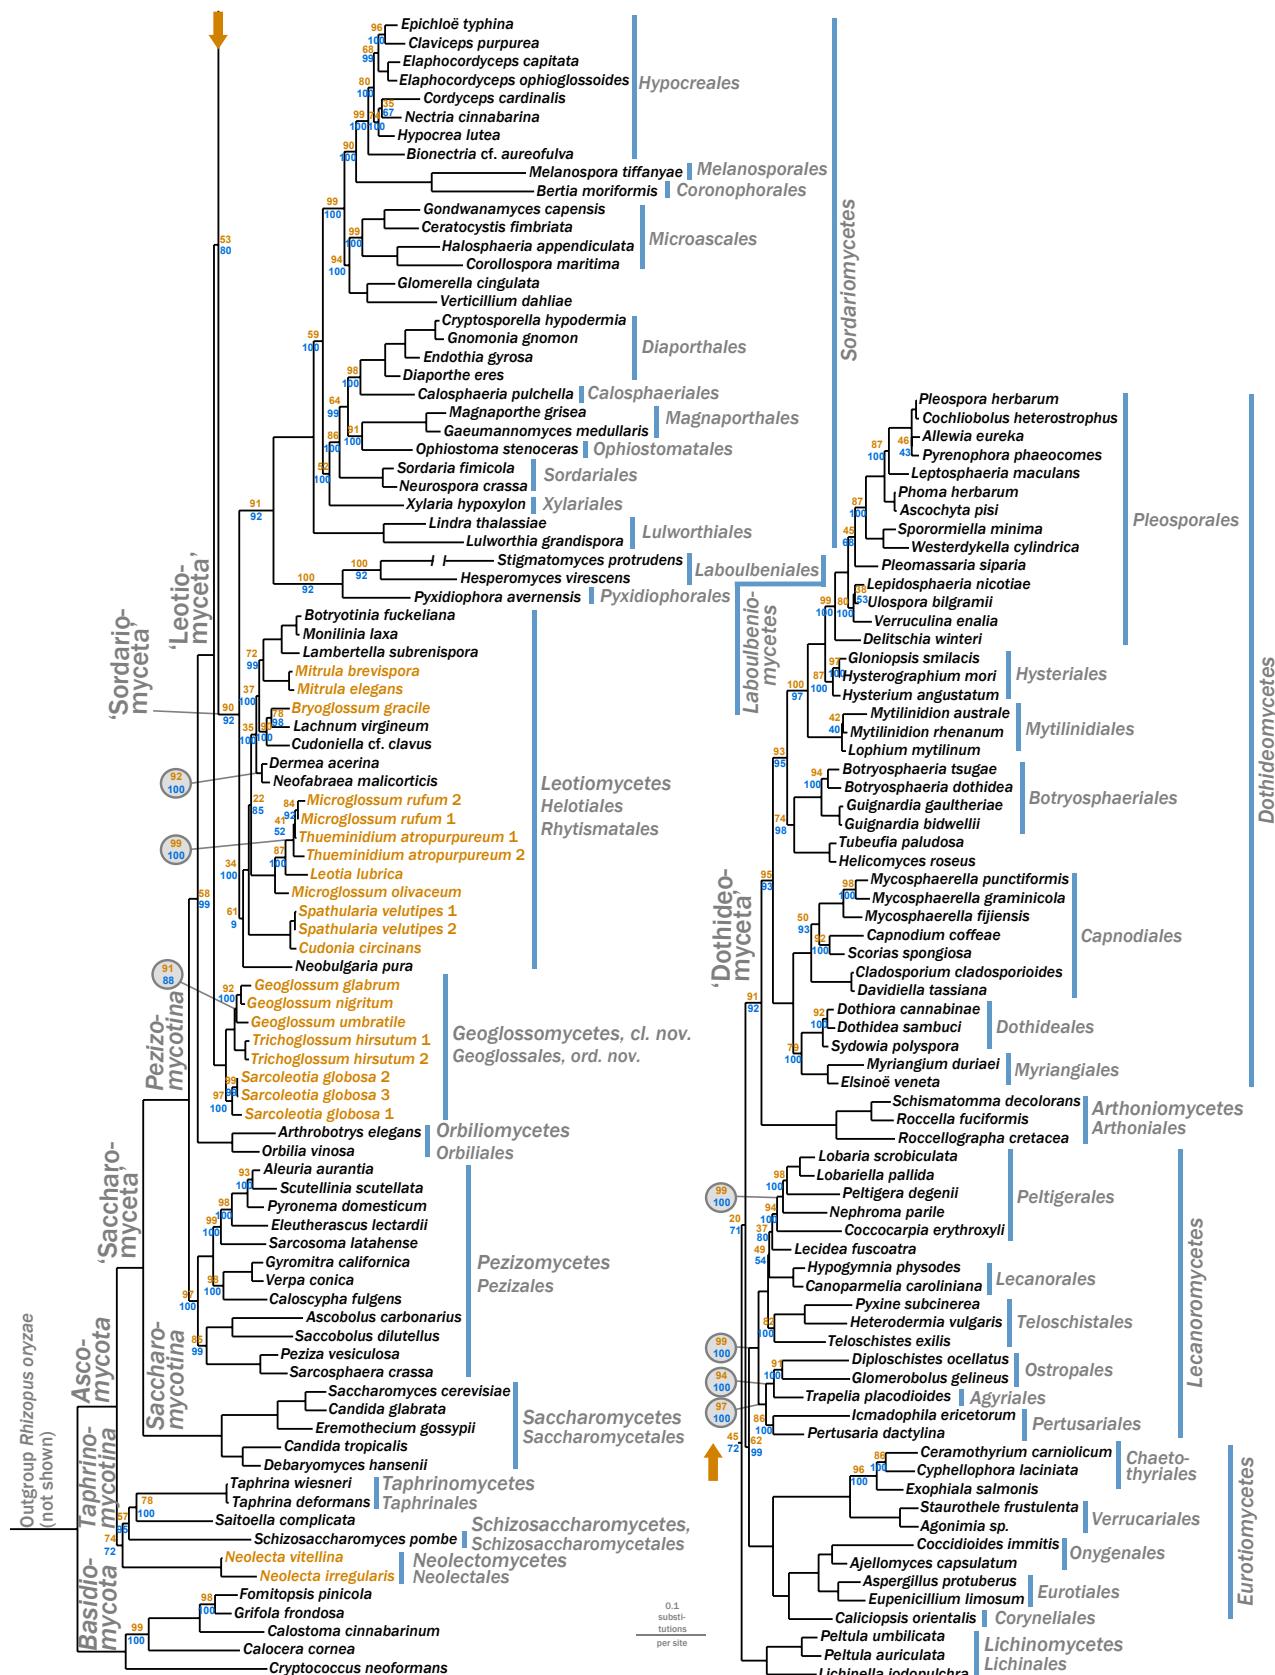

*Ascomata* solitaria vel gregaria, capitata, stipitata; stipe cylindricus, atrum, glabrum vel furfuraceus. Regio hymenali capitata, clavata vel pileata, indistinctum ex stipe; hymenium atrum, continuatum stipe ad praematu incrementi grado. Asci clavati, inoperculati, octospori, poro parvo in iodo caerulecentes. Ascospores elongatae, fuscae, pullae vel hyalinae, multi-septatae. Paraphyses filiformes, pullae vel hyalinae. Distributio generalis, terrestris, habita locis fere uliginoso et musoso.

*Type genus.* *Geoglossum* Pers., Neues Mag. Bot. 1: 116. 1794; *Geoglossaceae*.

*Ascomata* scattered to gregarious, capitate, stipitate; stipe cylindrical, black, smooth to furfuraceous. Ascigerous portion capitate, club-shaped to pileate, indistinguishable from stipe. *Hymenium* surface black, continues with stipe at early development stage. Asci clavate, inoperculate, thin-walled, J+, usually 8-spored. Ascospores elongate, dark-brown, blackish to hyaline, septate when mature. Paraphyses filiform, blackish to hyaline. Global distribution, terrestrial, habitat usually boggy and mossy.

## DISCUSSION

In keeping with the phylogeny presented in Fig. 1, we endorse use of the -myceta suffix in order to circumscribe well-supported clades above class. The numbers of these clades are limited, and the use of such taxa will continue to become more practical as our biological knowledge base broadens. Use of this suffix will also allow for the continued use of *Leotiomycetes*, a taxon that has already been defined with a Latin diagnosis provided as a ranked superclass (Eriksson & Winka 1997) and remains in use (Lumbsch et al. 2005, Wang et al. 2006a). We propose its continued use, but as a rankless taxon together with the newly proposed rankless taxa, 'Saccharomyceta', 'Dothideomyceta' and 'Sordariomyceta'. Since these taxa are not currently accepted under the Code (McNeill et al. 2006), we will refrain from formal designations. The relevant clades are discussed below with the informal designations indicated in single quotations.

**Fig. 2** A most likely tree obtained by RAxML for Ascomycota (as in Fig. 1). Phyla, subphyla, class, order and rankless taxa are indicated. Taxa designated as earth tongues are indicated in orange. The tree is displayed as two subtrees – orange arrows indicate where the subtrees were joined. The tree was rooted with outgroup *Rhizopus oryzae* (not shown). Bootstrap values are shown in orange above nodes and Bayesian posterior probabilities in blue below. Numbers were removed for nodes with 100 % bootstrap and 100 % posterior probability.

### **Subphylum Taphrinomycotina**

As in recent studies using large multi-gene datasets (Spatafora et al. 2006, Sugiyama et al. 2006, Liu et al. 2009, Schoch et al. 2009), we find ML bootstrap support here for the monophyly of the *Taphrinomycotina*. The addition of sequences from protein coding genes has been vital to the establishment of statistical support for this grouping. Recent work has shown that the short generation times characteristic of species in this group make phylogenetic analyses particularly susceptible to long branch attraction artefacts (Liu et al. 2009). The placement of *Neolecta* in this subclade is also confirmed here. The club-shaped apothecia of the members of *Neolecta* share superficial similarity with those of the *Geoglossaceae*. *Neolecta* was long thought to be included in the *Geoglossaceae* until molecular work proved otherwise (Landvik 1996). In support of its placement in this early diverging group, *Neolecta* has several presumably ancestral features, such as simplified non-poricidal ascospores without croziers and the absence of paraphyses (Redhead 1979, Landvik et al. 2003). With additional sampling of both taxa and genes we find here moderate support for the monophyly of *Taphrinomycotina*, and thus demonstrate that the earliest diverging clade of the *Ascomycota* was dimorphic, with both filamentous and yeast growth forms. Nevertheless, it remains apparent that this part of the *Ascomycota* tree remains under sampled. This lack of adequate sampling is supported by the recent description of a clade labelled 'Soil Clone Group I' (SCGI). SCGI is ubiquitous in soil and is only known from environmental sequence data (Porter et al. 2008). It appears possible that they form a novel early diverging lineage outside of *Taphrinomycotina*. Very little remains known about their ecology, morphology and general biology.

### **Rankless taxon 'Saccharomyceta'**

'Saccharomyceta' includes the two remaining subphyla of *Ascomycota*, *Saccharomycotina* and *Pezizomycotina*. *Saccharomycotina* comprises the 'true yeasts' (e.g., *Saccharomyces cerevisiae*), although hyphal growth has been documented in some taxa (e.g., *Eremothecium*). The *Pezizomycotina* consists of the majority of filamentous, ascoma producing species, but numerous species are additionally capable of yeast and yeast-like growth phases. Thousands of species are only known to reproduce asexually. These two subphyla form a well-supported, monophyletic group that has been recovered in a large number of studies across a diversity of character and taxon sets. The recognition of 'Saccharomyceta' highlights the shared common ancestry of these two taxa and the inaccurate characterisation of *Saccharomycotina* as a primitive or basal lineage of the *Ascomycota*. Rather, its small genome size (Dujon et al. 2004) and dominant yeast growth phase can be characterized as derived traits for this subphylum.

### **Rankless taxon 'Leotiomyceta'**

We apply 'Leotiomyceta' as a rankless taxon containing the majority of fungi with a diversity of inoperculate ascospores (e.g., fissitunicate, poricidal, deliquescent). 'Leotiomyceta' excludes the earliest diverging classes of *Pezizomycotina*, *Pezizomycetes* and *Orbiliomycetes*. It was first defined as a superclass (Eriksson & Winka 1997). This definition has remained in use (Lumbsch et al. 2005, Spatafora et al. 2006). Included in this clade are the informal, rankless taxa 'Dothideomyceta', 'Sordariomyceta', as well as the classes *Eurotiomycetes*, *Lecanoromycetes*, *Lichinomycetes*, and a newly proposed class, *Geoglossomycetes*.

The type genus of *Geoglossaceae*, *Geoglossum* was initially proposed by Persoon (1794). Persoon described it as club-shaped, with unitunicate, inoperculate ascospores, with the type species given as *Geoglossum glabrum* Pers. *Trichoglossum*

have historically been classified in *Geoglossaceae*, and *Sarcoleotia* has historically been classified in the *Helotiaceae* (*Leotiomycetes*). These inoperculate *Discomycetes* produce terrestrial, stipitate, clavate ascomata, commonly referred to as earth tongues, which include *Leotia*, *Microglossum*, *Cudonia*, and *Spathularia*. In terms of ascospore development, species of *Geoglossum*, *Trichoglossum*, and *Sarcoleotia* possess a hymenium that freely develops towards the base, while other earth tongue fungi feature a distinct ridge to their hymenium, implying a developmental stage during which the hymenium is enclosed (Schumacher & Sivertsen 1987, Spooner 1987, Wang et al. 2006b). An enclosed hymenium has been observed as well in several other lineages, such as *Cyttaria*, *Erysiphales* and *Rhytismatales* in the *Leotiomycetes* (Korf 1983, Gargas et al. 1995, Johnston 2001). Although the name earth tongue implies these fungi are terrestrial and have no direct association found with other organisms, *Trichoglossum*, *Geoglossum* and *Sarcoleotia globosa* have often been recorded in boggy habitats abundant with bryophytes (Seaver 1951, Dennis 1968, Schumacher & Sivertsen 1987, Spooner 1987, Jumpponen et al. 1997, Zhuang 1998). Ascospore apical morphology is one of the major features in distinguishing higher ascomycetes, and operculate ascomycetes as members of *Pezizales* have an apical or subapical operculum which is thrown back at spore discharge while a definite plug is present in the thickened 'inoperculate' ascospore apex as in species of the *Helotiales* (Korf 1973). Ultrastructure of the ascospore apical apparatus suggested no close relationship between *Leotia lubrica* and species of *Geoglossum* and *Trichoglossum*. A structure known as a tractus connects the uppermost spore to the apical wall and the spores to each other in *Trichoglossum hirsutum*, but is never found in other species of the *Helotiales* and is possibly homologous to structures in *Sordariomycetes* and *Pezizomycetes* (Verleyen 1994). Recent molecular phylogenetic analyses (Sandnes 2006, Wang et al. 2006a, b) confirmed that the earth tongue fungi are not monophyletic. At least two origins occurred in *Leotiomycetes*: in *Leotia* and allies in *Helotiales*, and in *Cudonia* and allies in *Rhytismatales*. *Geoglossum*, *Trichoglossum*, *Sarcoleotia* (*Geoglossomycetes* as we define it) represent a third, independent lineage of earth tongues, which we confirmed does not belong within the *Leotiomycetes*.

DNA-only and combined model analyses produced conflicting placements of *Geoglossaceae* within *Pezizomycotina*. Previous analyses applying nucleotide sequences only placed the order as a sister group to the *Lichinomycetes* (Lutzoni et al. 2004, Spatafora et al. 2006), which includes a small number of lichenised species mainly associated with cyanobacteria (Reeb et al. 2004). Our sampling of *Lichinomycetes* includes two genera, *Peltula* and *Lichinella* that encompass at least some of the ascospore diversity, i.e., rostrate and deliquescent, present in the class. In contrast, our combined amino acid and nucleotide model analyses resolved *Geoglossaceae* as an isolated, unique lineage of 'Leotiomyceta' with no supported sister relationship, in agreement with Schoch et al. (2009). Different levels of missing data underlie these two conflicting topologies, and several phenomena can potentially explain this conflict, ranging from model misspecification to long-branch attraction. Regardless of these concerns, our conclusion that the *Geoglossaceae* is a monophyletic lineage, unaligned with members of the *Leotiomycetes* and any of the other large fungal classes remains strongly supported.

*Eurotiomycetes* and *Lecanoromycetes* are the two remaining classes in 'Leotiomyceta'. *Eurotiomycetes* is arguably the most ecologically diverse class within *Ascomycota* including lichenised species, saprobes and pathogens of animals and plants. As currently defined, this class incorporates several distinct orders and three subclasses spanning virtually all known fun-

<sup>1</sup> voucher GB = obtained from GenBank or genome databases without clear voucher numbers

gal ecological niches (Geiser et al. 2006). *Lecanoromycetes* contain the majority of the lichenised fungi (Miadlikowska et al. 2006). Earlier large-scale phylogenies (e.g. Lutzoni et al. 2004) have suggested a sister relationship between these two classes, but we find that such a relationship remains without strong statistical support (Fig. 1). Despite this, internal nodes are well supported enough to provide good support for the hypothesis that lichenisation evolved multiple times in the *Ascomycota*, with losses being rare (Gueidan et al. 2008, Schoch et al. 2009).

The remaining classes are discussed in relation to their respective rankless taxa listed below.

#### **Rankless taxon 'Dothideomyceta'**

This taxon is well supported, with ML bootstrap of 91 % and a moderate Bayesian posterior probability of 92 %. It includes two classes of fungi which produce fissitunicate asci, *Arthoniomycetes* and *Dothideomycetes*. *Arthoniomycetes* consists of  $\pm$  1 600 species of lichenised and lichenicolous fungi with fissitunicate asci and exposed hymenia (Grube 1998, Ertz et al. 2009). Unlike other species with fissitunicate asci, these taxa have ascohymenial development, prompting their placement in a transitory group, or 'Zwischengruppe' that is intermediate between ascohymenial and ascocolocular development (Henssen & Jahns 1974). The class is resolved as sister to *Dothideomycetes*, consistent with recent studies (Lutzoni et al. 2004, Spatafora et al. 2006, Wang et al. 2006a). *Dothideomycetes* is a large class containing two subclasses, *Dothideomycetidae* and *Pleosporomycetidae* (Schoch et al. 2006). Our analysis contains members of all known orders in the class, including recent additions (Boehm et al. 2009). This broad representation yields increased resolution in the placement of an order previously labelled incertae sedis, *Botryosphaeraiales* (Schoch et al. 2006). Placement of *Botryosphaeraiales* within subclass *Pleosporomycetidae* is well supported, as is a close relationship with the unplaced family *Tubeufiaceae* (Fig. 2).

#### **Rankless taxon 'Sordariomyceta'**

'Sordariomyceta' contains three classes, *Leotiomycetes*, *Laboulbeniomycetes* and *Sordariomycetes*. We find similar resolution for this clade as for the 'Dothideomyceta'. These three classes are characterised by the production of unitunicate, poricidal asci, or derivatives of such asci (e.g., deliquescent asci). *Leotiomycetes* and *Sordariomycetes* include numerous fungi associated with plants as pathogens, endophytes and epiphytes. The sordariomycete phylogeny is comparatively well resolved with 15 orders and 3 subclasses named (Zhang et al. 2006, Kirk et al. 2008). In contrast, the leotiomycete classification still poorly matches its inferred phylogeny. A recent class-wide effort to assess morphological and ecological data in a phylogenetic context continued to find high levels of diversity unaccounted for in the current classification (Wang et al. 2009). In addition to the aforementioned two classes, Fig. 1 also supports the placement of the *Laboulbeniomycetes* reported in Schoch et al. (2009) as part of a monophyletic lineage. The relationship between the *Sordariomycetes* and *Laboulbeniomycetes* is also well supported but we will refrain from naming this node until sampling can be expanded for the *Laboulbeniomycetes*. The class *Laboulbeniomycetes* encompasses an enigmatic lineage of insect symbionts and mycoparasites that have long proved problematic with respect to placement in higher-level classification schemes. *Laboulbeniomycetes* comprises two orders, *Laboulbeniales* and *Pyxidiophorales*, that are united by an ascospore synapomorphy of a darkened holdfast region and by molecular data (Weir & Blackwell 2001, 2005). Members of *Pyxidiophorales* possess globose perithecia with a single

layer of wall cells, and long perithecial necks that release their ascospores passively in droplets at the tips of their necks; this mechanism is repeatedly derived within *Ascomycota* for insect dispersal of ascospores (Blackwell 1994). For this reason, they have been likened to other insect-dispersed perithecial ascomycetes (e.g., *Ophiostomatales*) that now are strongly supported as members of *Sordariomycetes*. *Laboulbeniales* includes ectoparasites of insects and displays morphological traits not found elsewhere in the *Ascomycota*. They form apomorphic ascocarps produced by the division and enlargement of ascospores that are difficult to characterize in existing ascocarpal terms. *Laboulbeniales* feature an ostiole, however, which is consistent with perithecia produced by hyphal growth. Determinate growth of the ascospore with a series of predictable cell divisions produces a thallus of a finite number of cells that is characteristic at the genus and species level (Tavares 1979). The analyses presented here strongly support *Laboulbeniomycetes* as sister to *Sordariomycetes*. This placement corresponds with the terminology originally applied to this group (Thaxter 1896). It is interesting to note that while species of *Pyxidiophorales* are endowed with a diverse group of anamorphs, members of *Laboulbeniales* are mainly known to reproduce sexually.

#### **Summary**

In conclusion, we propose two monotypic formal taxa and describe continued support for four informal rankless taxa. Important improvements in the resolution of deep nodes within the *Ascomycota* may be attributed to multi-gene sequence data produced by AFTOL and other projects during the last 5 years. The accelerating accumulation of genome-scale sequence data will continue to challenge and improve existing phylogenetic hypotheses. However, in order to direct limited resources towards under-sampled areas in the fungal phylogeny, an accurate, up-to-date classification is required. By placing three earth tongue genera in a separate newly described class, we underscore and communicate the genetic diversity that is found in the fungi producing these very convergent morphologies.

**Acknowledgements** We are grateful to Kentaro Hosaka, Dan Luoma and Zhiliang Yang for the photographs used. We acknowledge funding provided by NSF through a grant (DEB 0717476) to J.W.S. and C.L.S. (while at Oregon State). C.L.S. was also supported in part by the Intramural Research program of the National Institutes of Health. Z.W. was supported by the Yale University Anonymous Postdoctoral Fellowship.
